(Received 18 February 2008; final version received 6 May 2008)

The generation of entangled photon pairs by parametric down-conversion from solid state CW lasers with small coherence time is theoretically and experimentally analyzed. We consider a compact and low-cost setup based on a two-crystal scheme with Type-I phase matching. We study the effect of the pump coherence time over the entangled state visibility and over the violation of Bell’s inequality, as a function of the crystal length. The full density matrix is reconstructed by quantum tomography. The proposed theoretical model is verified using a purification protocol based on a compensation crystal.

Keywords: down-conversion; entanglement; coherence time; quantum tomography

1. Introduction

Generation of entanglement is the key ingredient of quantum information processing. In optical implementation with discrete variables the standard source of entangled photon pairs is parametric down-conversion in nonlinear crystals pumped by a single-mode laser [1,2]. Recent advances in laser diode technology allow the realization of simpler and cheaper apparatuses for the entanglement generation [3,4], though the quality of the resulting photon pairs is degraded by the small coherence time of the pump laser.

In this paper we address theoretically and experimentally the generation of entanglement using a laser diode pump as well as its application to visibility and nonlocality tests. We focus on the effects of the small coherence time and implement a purification protocol based on a compensation crystal [5] to improve entanglement generation. We reconstruct the full density matrix by quantum tomography and analyze in detail the properties of the generated state, including purity and visibility, as a function of the crystal length and the coherence time of the pump. The topic is relevant for applications for at least two reasons. On one hand, quantifying the degree of entanglement is of interest in view of large scale application. On the other hand, a detailed characterization of the generated state allows one to suitably tailor entanglement distillation protocols.

The paper is structured as follows: in Section 2 we describe the experimental apparatus used to generate entanglement, whereas Section 3 is devoted to illustrate in detail the quantum state of the resulting photon pairs in the ideal case. The effects of small coherence time are analyzed in Section 4 and the experimental characterization of the generated states is reported in Section 5. Section 6 is devoted to nonlocality test whereas Section 7 closes the paper with some concluding remarks.

2. The experimental apparatus

A scheme of the experimental apparatus is shown in Figure 1. The ‘state generator’ consists of two identical BBO crystals, each cut for Type-I down-conversion, one half-wave plate (HWP) and one quarter-wave plate (QWP) as implemented in [6]. The crystals are stacked back-to-back, with their axes oriented at 90° with respect to each other [1,3]. The balancing and the phase of the entangled states are selected by changing the HWP and QWP orientation.

The crystals are pumped using a 40 mW, 405 nm laser diode (Newport LQC405-40P), with a spectral line that is typically broadened by phonon collisions. The coherence time of the pump light τc, which is a fundamental parameter for our experiment, is 544 fs and corresponds to a spectral width around 0.3 nm. We obtained this important information with a standard measurement of the first-order correlation function. The generated photons are analyzed using adjustable QWP, HWP and a polarizer [7]. Finally light signals are focused into multimode fibers which are used to direct the photons to the detectors. The detectors are
home-made single photon counting modules (SPCM),
based on an avalanche photodiode operated in Geiger
mode with active quenching. For the coincidence
counting we use a TAC/SCA.

The nonlinear crystals are properly cut to generate
photons into a cone of half-opening angle 3.0° with
respect to pump. The first crystal converts horizontally
polarized pump photons into vertically polarized (V)
signal and idler photons, while the second crystal
converts vertically polarized pump photons into hori-
zontally polarized (H) signal and idler photons. This
configuration introduces a delay time τ, depending on
the crystal length, between the V and the H part of the
entangled state, as discussed in the following sections.

3. The state vector of the generated entangled
photons

The pair of photons generated by SPDC of Type
I from a single nonlinear crystal, having wave vectors
\( \mathbf{k}_s \) and \( \mathbf{k}_i \), are represented by state vectors \( |\mathbf{k}_s\rangle_0 \) and \( |\mathbf{k}_i\rangle_0 \)
for the signal and idler, respectively. The wavefunction
appropriate to these state vectors \([8–10]\):

\[
\Psi = \frac{1}{\sqrt{2 \pi}} \int d^3 \mathbf{k}_s d^3 \mathbf{k}_i A(\omega_p - \Omega_p^0) F(\Delta k_s) F(\Delta k_i)|\mathbf{k}_s\rangle_0 |\mathbf{k}_i\rangle_0,
\]

where \( A(\omega_p - \Omega_p^0) \) is the spectral complex amplitude of
the pump laser, which is a function of the pump
frequency \( \omega_p(k_p) = \omega_s(k_s) + \omega_i(k_i) \), assuming as usual
the validity of the energy conservation in the genera-
tion process, and it is centered around the reference
frequency \( \Omega_p^0 \). The factors \( F \) and \( f \) are mismatch
functions depending on the variation of the transverse
and longitudinal part of the pump wave vector with
respect to the reference of momentum conservation,
and are described in detail in the following.

The function \( F(\Delta k_s) \) comes from a spatial integra-
tion over all the possible processes of photon genera-
tion within the pump transverse profile in the crystal,
taking the first-order approximation of the nonlinear
interaction. For a Gaussian pump profile we obtain
again a Gaussian function, with a width varying as the
inverse of the beam waist \( w \):

\[
F(\Delta k_s) = \exp(-w^2 \Delta k_s^2/4),
\]

where, referring to Figure 2, one has

\[
\Delta k_s = k_s(\Theta_s) \sin(\theta_s) - k_i(\Theta_i) \sin(\theta_i)
\]

with the internal generation angles \( \Theta_s \) and \( \Theta_i \) for signal
and idler, respectively. In our case the pump beam
waist is near 2 mm, therefore we can consider exact
transverse momentum conservation to a good approx-
imation. In fact it is easy to verify that with this beam
waist we have an angular Gaussian width of 0.006°
around the reference internal angles \( \Theta_s = \Theta_i = 1.8° \)
(derived from external angles \( \text{ext} = \Theta_i = 3.0° \) using
Snell’s law), very small with respect to the acceptance
angle of 0.074° FWHM of the optical coupling devices.

The conservation of the transverse wave vector permits
one to simplify the geometry of the system, by conside-
ring in the following a generation angle, say \( \theta_i \), as a function of the other quantities \( \Theta_s, \Theta_i, \Theta_s \).

The mismatch function \( f(\Delta k_i) \) has the same
meaning as \( F \), but derives from an integration along
the crystal length \( L_C \), and reads:

\[
f(\Delta k_i) = \frac{\sin(\Delta k_i L_C/2)}{\Delta k_i L_C/2}
\]
where
\[ \Delta k_1 = k_p(\omega_p) - k_s(\omega_s) \cos(\theta_s) - k_i(\omega_i) \cos(\theta_i(\omega_s, \omega_i)). \]

As a matter of fact the pump spectrum width, determining the visibility effects, is very small with respect to the spectral width of the down-conversion; this means that \( f \) is slightly dependent on \( \omega_p = \omega_s + \omega_i \), as can be verified numerically. We will not consider such a dependence by substituting \( \omega_p \) with the reference pump frequency \( \Omega_p^0 \) as the argument of \( f \). This approximation turns out to be very good for crystal lengths below a few millimetres, but around 3 mm (our maximum crystal length) the conservation of the longitudinal wave vector starts to shrink the down-conversion spectrum. A similar consideration can be given for the dependence of \( f \) over the internal angle \( \theta_i \); since the experimental configuration is highly collinear, the optical couplers are practically insensitive to its variation (within the acceptance cone). Therefore, we can substitute \( \theta_i \) with the fixed reference angle \( \theta_o \), and the mismatch function becomes:
\[ f(\omega_p, \omega_s, \theta_o) \approx f(\Omega_p^0, \omega_s, \omega_i) \equiv f(\omega_i). \] (4)

The wavefunction of the photon pair can now be written in the more simple form:
\[ |\Psi\rangle = \int d\omega_p d\omega_s d\omega_i A(\omega_p - \Omega_p^0) f(\omega_s) |\omega_s, \omega_i\rangle_1 |\omega_p\rangle_2, \] (5)

In the first approximation we can solve for the integral over the internal generation angle \( \theta_i \) because neither \( A \) nor \( f \) depend on it, but a more refined reasoning put forward the fact that the conservation of the transverse wave vector introduces a limitation in the effective spectral width of the mismatch function, hence affecting the integration over \( \omega_i \). This happens because by varying \( \omega_i \) around the down-converted reference \( \Omega_p^0/2 \), the idler angle \( \theta_i \) may go outside from the optical coupler acceptance limit, as verified by means of the experimental data discussed in Appendix 1. This problem does not affect the integral over \( \omega_p \), for the smallness of the pump spectral width. To take care of this spectral limitation we introduce a correction factor \( R(\Omega_p^0/2, \Delta \omega_i) \) centered around the reference \( \Omega_p^0/2 \) and having the limited spectral width \( \Delta \omega_i \) (see Appendix 1). Defining \( f(\omega_i) = f(\omega_i) \cdot R \), we arrive at this wavefunction for the photon pairs:
\[ |\Psi\rangle = \int d\omega_p d\omega_s A(\omega_p - \Omega_p^0) f(\omega_s) |\omega_s, \omega_i\rangle_1 |\omega_p - \omega_i\rangle_2. \] (6)

This expression is used to construct the proper wavefunction (or the proper state vector) for the entangled state generated in our experiment using the pair of oriented crystals [1,3], as described in the previous section. In particular we consider a suitable superposition of the single crystal wavefunctions of Equation (6), introducing the degree of freedom of polarization on state vectors, because the first crystal generates a vertical polarized (\( VV \)) and the second crystal generates a horizontal polarized (\( HH \)) photon pairs, respectively. Moreover, we have a delay time between these pairs, due to the different optical length of the photon trajectories in the inner of crystals. This can be represented in the model by assuming photon generation in the crystals’ middle [11,12] (in Appendix 2 we show that this is a very good approximation) and introducing propagation factors for the internal state transport.

In the Figure 3 a sketch of the geometry for entangled photon generation is shown, limited for clarity to the signal trajectories. In the first crystal \( V \) photons are generated, the state is \( |V, \omega_o\rangle_1 |V, \omega_p - \omega_o\rangle_2 \), and the complex exponential for the product of the signal and idler propagation factor (as required by the form of Equation (6)) till to exiting the crystal is given by:
\[ P(V) = \exp \left\{ i L \left[ k_p^2(\omega_o) \frac{1}{2 \cos(\phi_1)} + k_i^2(\omega_p - \omega_o) \frac{1}{2 \cos(\phi_1)} + k_i^2(\omega_o - \omega_p) \frac{1}{2 \cos(\phi_2)} + k_i^2(\omega_o) \frac{1}{2 \cos(\phi_2)} \right] \right\}. \] (7)

where the superscripts ‘o’ and ‘e’ on wave vectors indicates ordinary and extraordinary propagation, and the angles \( \phi_1 = 1.807 \), \( \phi_2 = 1.84 \) can be found using the laws of wave rays in birefringent crystals [13] and Snell’s law, under the request of an exit angle of \( 3^\circ \). For the second crystal, in which \( H \) photons are generated
and the state is |H, \omega_\lambda\rangle,|H, \omega_p - \omega_\lambda\rangle, the respective propagation factor is:

\[ P(H) = \exp \left\{ i \frac{\mathcal{L}}{2} \left[ \frac{k_p^2(\omega_p)}{2} + \frac{k_s^2(\omega_p)}{2} + k_s^2(\omega_\lambda) \frac{1}{2\cos(\phi_3)} \right] + k_s^2(\omega_p - \omega_\lambda) \frac{1}{2\cos(\phi_3)} \right\}. \]  

(8)

where \phi_3 = 1.806, and is included in the propagation of the pump ray from the generation point of the (VV) pair (note that \phi_3 is slightly different from \phi_2 due the different refraction index for ‘o’ and ‘e’ propagation). The entangled state wavefunction is therefore:

\[ |\Psi\rangle = \int d\omega_p \, d\omega_{\lambda} \Lambda(\omega_p - \Omega_{\lambda}) f(\omega_\lambda) \]

\[ \times \frac{1}{2^{1/2}} \left\{ P(H) |H, \omega_\lambda\rangle,|H, \omega_p - \omega_\lambda\rangle + P(V) |V, \omega_{\lambda}\rangle,|V, \omega_p - \omega_\lambda\rangle \right\}. \]  

(9)

This expression can be recast in a more useful form in the following way. Let’s write the frequencies as \omega_p = \Omega_p + \Omega_p', \omega_\lambda = \Omega_{\lambda} + \Omega (with of course \Omega_p' = 2\Omega), where \Omega_p and \Omega represent the frequency shift with respect to reference to the pump and for the down-conversion, respectively. Now, in the propagation factors we introduce a first-order approximation for the wave vectors putting:

\[ k_p(\omega_p) \approx k(\Omega_p) + \Omega_p/V_p, \quad k_s(\omega_\lambda) \approx k(\Omega_\lambda) + \Omega/V, \]

\[ k_s(\omega_p - \omega_\lambda) \approx k(\Omega_p') + \Omega_p'/V - \Omega/V', \]

where \(V_p\) and \(V\) are the proper group velocities of the pump and of the down converted signal, and these relations must be considered both for the ordinary wave and for the extraordinary wave. With these substitutions, and rewriting for future convenience the quantum states by factorizing the polarization part from the frequency one, the final form of the wavefunction Equation (9) read:

\[ |\Psi\rangle = \int d\Omega_p \, d\Omega_{\lambda} \Lambda(\Omega_p) \frac{1}{2^{1/2}} \]

\[ \times \left\{ \exp[i(\phi_H + \tau_H \Omega_p)] |H, \Omega_p\rangle |\Omega_{\lambda}\rangle,|\Omega_p - \Omega_{\lambda}\rangle + \exp[i(\phi_V + \tau_V \Omega_p)] |V, \Omega_{\lambda}\rangle,|\Omega_p - \Omega_{\lambda}\rangle \right\}. \]  

(10)

where the phase terms coming from propagation factors are the sum of a constant phase:

\[ \phi_H = \left\{ k_s^2(\Omega_p) + k_s^2(\Omega_{\lambda}) + \frac{2k_s^2(\Omega_p')}{\cos(\phi_{3})} \right\} \frac{\mathcal{L}}{2}, \]

\[ \phi_V = \left\{ \frac{2k_s^2(\Omega_p')}{\cos(\phi_{1})} + \frac{4k_s^2(\Omega_{\lambda})}{\cos(\phi_{3})} \right\} \frac{\mathcal{L}}{2}, \]

and frequency dependent terms \(\tau_H \Omega_p, \tau_V \Omega_p\) containing the total propagation time inside the crystals:

\[ \tau_H = \left\{ \frac{1}{V_p} + \frac{1}{V_p} + \frac{1}{V_{\lambda} \cos(\phi_{3})} \right\} \frac{\mathcal{L}}{2}, \]

\[ \tau_V = \left\{ \frac{1}{V_{\lambda} \cos(\phi_{1})} + \frac{2}{V_{\lambda} \cos(\phi_{3})} \right\} \frac{\mathcal{L}}{2}. \]

It is important to note that these delay factors depend on pump frequency (not on the down converted frequency); this fact can be interpreted saying that the states (HH) and (VV) exiting the crystals are generated from the pump in two different temporal events in the past, depending on the different trajectories across the crystals. For all these four phase factors, their numerical value are determined from the data on refraction indexes and group velocities taken from [14], and listed in Table 1.

As a final observation, we note that in writing the final expression for the wavefunction Equation (10), it has discarded the variation of the propagation factors with respect to the propagation angles. Due to small angular acceptance of the detectors, it is possible to verify that, with excellent approximation, this dependence does not introduce any relevant effect.

4. The polarization density matrix

For the calculation of the density matrix and the complete characterization of the wavefunction it is important to define at best the statistical properties of the CW pump radiation, because our experimental data depend strongly on its coherence length. In the temporal domain, this light is characterized by a constant amplitude \(A_0\) and a rapidly varying phase.
with a characteristic time equal to the coherence time of the pump $\tau_0$. Therefore we can write:

$$d\omega P(\omega)\exp(i\omega t) = A_0 \exp(i\delta(t)), \quad (11)$$

where the pump amplitude in the temporal domain is expressed as the Fourier transform of the complex spectral amplitude, with $\delta(t)$ as a proper fluctuating phase.

Our experiment mainly concerns the reconstruction of the density matrix of the entangled system on the basis composed by the four signal and idler polarization combinations $HH$, $HV$, $VH$, $VV$. The relative density operator $\rho$, from which we derive the reduced density matrix on this polarization basis, is obtained from the full density operator $\rho_{00} = \langle \Psi | \Psi \rangle$ by tracing the degree of freedom on the frequencies, e.g. by integrating over the frequency state matrix elements:

$$\rho = \int d\omega' P(\omega')\langle \omega | \Psi \rangle \langle \Psi | \omega'\rangle \langle \omega' | \omega \rangle,$$

(12)

corresponding to the fact that we do not perform frequency measurements.

The form of the wavefunction in Equation (10) implies that only four elements of the $4 \times 4$ reduced density matrix are different from zero. Using the general relation $\langle \omega | \omega \rangle = \delta (\omega - \omega')$, we straightforwardly obtain for the first diagonal element:

$$\rho_{HH,HH} = \frac{1}{2} \int d\omega f(\omega)^2 \int d\omega P(\omega)\langle \omega | \Psi \rangle \langle \Psi | \omega \rangle = \frac{1}{2} \frac{A_0^2 \Delta T}{2\pi}, \quad (13)$$

where we put $\epsilon = \int |f(\omega)|^2$ and $\int d\omega P(\omega)\langle \omega | \Psi \rangle \langle \Psi | \omega \rangle = A_0^2 (\Delta T/2\pi)$ where $\Delta T$ is a large time interval. With similar calculation the other nonzero diagonal element results in $\rho_{VV,VV} = \rho_{HH,HH}$, as expected by symmetry arguments.

For the two off diagonal elements one has $\rho_{HH,VV} = \rho_{VV,HH}$, and in particular:

$$\rho_{HH,VV} = \frac{1}{2} \int d\omega f(\omega)^2 \int d\omega P(\omega)\langle \omega | \Psi \rangle \langle \Psi | \omega \rangle \exp[-i(\phi_H - \phi_V)] \exp[-i\omega_0(\tau_H - \tau_V)]$$

$$= \frac{1}{2} \epsilon \exp(-i\phi) \int d\omega P(\omega)\langle \omega | \Psi \rangle \langle \Psi | \omega \rangle \exp[-i\omega_0(\tau_H - \tau_V)], \quad (14)$$

where $\phi = \phi_H - \phi_V$.

With the Wiener–Khinchin theorem the frequency integral can be recast as a two time correlation function over the interval $\Delta T$, very large with respect to the coherence time of the pump, and smaller than the detector characteristic time:

$$\int d\omega P(\omega)\langle \omega | \Psi \rangle \langle \Psi | \omega \rangle \exp[-i\omega_0(\tau_H - \tau_V)]$$

$$= A_0^2 \frac{\Delta T}{2\pi} \int \frac{1}{\Delta T} \int d\omega [\exp[-i\delta(t) + i\delta(t - (\tau_H - \tau_V))]]$$

$$= A_0^2 \frac{\Delta T}{2\pi} \exp(-\Delta \tau/\tau_0), \quad (15)$$

where $\Delta \tau = |\tau_H - \tau_V|$, and the result is taken from [15]. If $\Delta T \gg \tau_0$, we have an incoherent superposition of random phases and the average of the complex exponentials tends to zero, otherwise we have a coherent sum, and the integral tends to one.

Finally, setting the state generator QWP in order to have $\phi = 0$ (see [1]) and putting for simplicity $p = \exp(-\Delta T/\tau_0)$, the reduced density matrix is:

$$\rho = \frac{\epsilon}{2} \begin{pmatrix} 1 & 0 & 0 & \frac{1}{2} \rho \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ \frac{1}{2} \rho & 0 & 0 & \frac{1}{2} \end{pmatrix}, \quad (16)$$

which can also be conveniently derived from a sum of two distinct density matrices, one of a pure entangled state and the other of a statistical mixture: $\rho = (\rho_1 + (1 - p)\rho_0)$ with $\rho_{HH} = (1/2)|HH\rangle \langle HH| + (1/2)|VV\rangle \langle VV|$. This is the more suitable form used for a comparison between theory and experimental data.

5. Experimental tomographic reconstruction of the density matrix and correlation visibility

In order to fully characterize the generated states at the quantum level we employ quantum tomography of their density matrices [16]. The experimental procedure goes as follows: upon measuring a set of independent two-qubit projectors $P_\mu = |\psi_\mu\rangle \langle \psi_\mu| \ (\mu = 1, \ldots, 16)$ corresponding to different combinations of polarizers and phase-shifters, the density matrix may be reconstructed as $\rho = \sum_\mu p_\mu \Gamma_\mu$, where $p_\mu = \text{Tr} \ [\rho P_\mu]$ are the probabilities of getting a count when measuring $P_\mu$ and $\Gamma_\mu$ is the corresponding dual basis, i.e. the set of operators satisfying $\text{Tr} \ [P_\mu \Gamma_\nu] = \delta_{\mu\nu} \ [17]$. Of course in the experimental reconstruction the probabilities $p_\mu$ are substituted by their experimental samples, i.e. the
frequencies of counts obtained when measuring $P_\mu$. In order to minimize the effects of fluctuations and avoid non-physical results we use maximum-likelihood reconstruction of two-qubit states [7,18]. At first we write the density matrix in the form

$$\hat{\rho} = \hat{T}^+ \hat{T},$$  \hspace{1cm} (17)

which automatically guarantees that $\hat{\rho}$ is positive and Hermitian. The remaining condition of unit trace $\Tr \hat{\rho} = 1$ will be taken into account using the method of Lagrange multipliers. In order to achieve the minimal parametrization, we assume that $\hat{T}$ is a complex lower triangular matrix, with real elements on the diagonal. This form of $\hat{T}$ is motivated by the Cholesky decomposition known in numerical analysis [19] for an arbitrary non-negative Hermitian matrix. For an $M$-dimensional Hilbert space, the number of real parameters in the matrix $\hat{T}$ is $M + 2M(M - 1)/2 = M^2$, which equals the number of independent real parameters for a Hermitian matrix. This confirms that our parametrization is minimal, up to the unit trace condition.

In numerical calculations, it is convenient to replace the likelihood functional by its natural logarithm, which of course does not change the location of the maximum. Thus, the function subjected to numerical maximization is given by

$$L(\hat{T}) = \sum_{k=1}^N \ln \Tr (\hat{T}^+ \hat{T} P_\mu) - \lambda \Tr (\hat{T}^+ \hat{T}),$$  \hspace{1cm} (18)

where $\lambda$ is a Lagrange multiplier accounting for normalization of $\hat{\rho}$ that equals the total number of measurements $N$. This may be easily proved upon writing $\hat{\rho}$ in terms of its eigenvectors $|\phi_i\rangle$ as $\hat{\rho} = \sum_i \gamma_i^2 |\phi_i\rangle \langle \phi_i|$, with real $\gamma_i$, the maximum likelihood condition $\partial L/\partial \gamma_i = 0$ reads

$$\lambda \gamma_i = \sum_{k=1}^N \frac{y_i |\phi_i\rangle \langle \phi_i|}{\Tr (\hat{T}^+ \hat{T} P_\mu)},$$  \hspace{1cm} (19)

which, after multiplication by $y_i$ and summation over $\nu$, yields $\lambda = N$.

The above formulation of the maximization problem allows one to apply standard numerical procedures for searching for the maximum over the $M^2$ real parameters of the matrix $\hat{T}$. The examples presented below use the downhill simplex or the simulated annealing methods [20]. Results of the reconstruction are reported for crystals with three different thicknesses, precisely 0.5, 1 and 3 mm, and in the case of compensation of the delay time between generated photons, as discussed later. Moreover, we present an analysis on the direct measurement of the visibility of the entangled state.

Data on correlation visibility are simply obtained by removing the HWP and QWP plates of the tomographic analyzer (see Figure 1) and detecting the signal and idler coincidence counts in a time interval, as a function of the signal polarizer angle, and having fixed the idler polarization angle at 45°. The theoretical prediction is:

$$P(\xi_s, 45°) = \langle 45° | \rho (\xi_s) | 45° \rangle^2 = \frac{1}{2} P(\cos (\xi_s - 45°))^2 + \frac{1}{4} (1 - P),$$  \hspace{1cm} (20)

where $\xi_s$ is the angle of the signal polarizer in the counter-clockwise direction, with the horizontal axis as the $0°$ reference. As is apparent from this formula, when $P$ is near unity (delay time smaller with respect to the coherence time of the pump) the oscillating contribution due to the non-local correlations is dominant. Conversely, with greater delay time (and small $P$) the correlations are washed out and the result is that of a statistical mixture which does not depend on the angle. In particular, the maximum of $P(\xi_s, 45°)$ is at 45°, while the minimum is at 135°, hence we can write explicitly the visibility $V$ of the oscillation as:

$$V = \frac{P(45°, 45°) - P(135°, 45°)}{P(45°, 45°) + P(135°, 45°)} = p.$$  \hspace{1cm} (21)

In Figure 4 we show the visibility measurements as a function of the signal polarizer angle for the three different crystal pairs, with the theoretical prediction of Equation (21) indicated by a full line. The comparison between the theoretical density matrix elements of Equation (16) and their tomographic reconstruction from experimental data is shown in Figure 5. It is confirmed that the off-diagonal elements tend to reduce in magnitude for larger crystal thickness; in particular for 3 mm crystals we obtain the density matrix of a statistical mixture. This is worth nothing since in this case it is very difficult to find the proper alignment of the QWP because of very low visibility; this fact could justify the difference between the observed visibility and the expected one.

The general behavior is confirmed also by the calculation of entanglement, as measured by concurrence [21], which gives $C_{0.5} = 0.635$, $C_{1.0} = 0.473$, and $C_{3.0} = 0.002$, respectively, using the reconstructed values of the density matrix elements.

In our model the lack of visibility of the entangled state is fully ascribed to the decoherence effect due to the fluctuating phase difference between $H$ and $V$ parts of the SPDC, depending on the delay $\Delta t$. Having a very small area of the fiber collimator, we have neglected any decoherence of spatial origin, which
introduces a phase variation depending on the detector viewing angle. In order to verify this statement, we have performed a series of measurements with the 3 mm crystal, putting windows of 0.5 mm linear aperture in front of the collimators: if the decoherence had a spatial contribution, we would have expected an increase in the state purity. In fact, the results of the state reconstruction were the same as the original configuration, thus supporting our hypothesis.

This fact also suggests how to improve the purity of the entangled state by a phase retardation on the $H$ polarized part of the pump with respect to the $V$ polarized part [5]. This can be accomplished by inserting, along the pump ray and before the state generator, a properly oriented birefringent crystal with a suitable length. In this way we introduce on the pump two different delay times $\tau_H$ and $\tau_V$, with $\tau_H^V - \tau_V^H = [(1/V_H^V) - (1/V_V^V)]L_{\text{comp}}$, where $L_{\text{comp}}$ is the compensation crystal length, and $V_H^V$ and $V_V^V$ are the pump group velocities. These delays must be summed to the original delay times $\tau_H$ and $\tau_V$, to obtain a new $\Delta \tau = |\tau_H - \tau_V + \tau_H^V - \tau_V^V|$ which must be set equal to zero to obtain maximum visibility. This condition of perfect compensation requires selecting proper crystal length and orientation.

With the BBO crystals used in our lab it was possible to achieve partial compensation, and only in one selected configuration. We performed a series of measurements using the 1 mm double crystal as state generator, and a 3 mm single crystal as pump phase retarder. The length of this crystal is near to the ideal one, but we can not select the better orientation for the principal axis because it is too similar to the phase matching angle for the SPDC generation.

The visibility is expected to vary from a maximum to a minimum for a 90° change in compensation crystal orientation with respect to the longitudinal axis, as confirmed by the tomographic reconstruction shown in

6. Measurements on the violation of Bell’s inequality

We have also performed a series of measurements of the $S$ parameter, characterizing the Bell’s inequality in the CHSH version [23], for a comparison with the prediction of our theoretical model. To obtain reliable data on the $S$ parameter we used the same experimental apparatus previously employed for correlation measurements. We considered as usual the 16 different configurations of the polarization angles on the signal and on the idler [3].

The Bell $S$ parameter is theoretically defined as:

$$ S = E(a, b) - E(a, b') + E(a', b) + E(a', b'), $$

(22)

where the arguments $a$, $a'$ and $b$, $b'$ are the selected angles for signal polarizer and idler polarizer, respectively. The function $E$ is defined as $E(a, b) = P(a, b) + P(a^\perp, b^\perp) - P(a, b^\perp) - P(a^\perp, b)$, where $a^\perp = a + 90^\circ$ and $b^\perp = b + 90^\circ$. The function $P$ is exactly that described in Equation (20), but with the idler angle specified by the argument. For any realistic local theory one has $|S| \leq 2$, while for quantum mechanics $|S|$ can be greater than 2, reaching a maximum value of $2(2^{1/2})$. The following choice for the angles is used: $a = 0^\circ$, $b = \theta$, $a' = b + \theta$ and $b' = a + \theta$. In this way $S$ is a function of the angle $\theta$ alone. In Figure 7 we show the calculated $S(\theta)$ for three states with different visibility $\mathcal{V} = p = (1, 0.7, 0.5)$; by decreasing $p$, the values of $S$ tend to return in the limit of a local theory.

For a comparison with these results of our model, we have measured the $S$ parameter for three different angles using as state generator the pair of 0.5 mm crystals, that is the case with higher visibility. In Figure 8 we show the theoretical curve of the $S$ parameter for a visibility equal to 0.77 (full line), together with two other curves (dashed lines) indicating the extremal of the experimental errors, relative to the limited number of counts during data acquisition. The three measurements of $S$ for the angles of $16^\circ$, $24^\circ$, $40^\circ$ are indicated with error bars. In particular we get $S(16^\circ) = 2.38 \pm 0.03$, $S(24^\circ) = 2.417 \pm 0.025$ and $S(40^\circ) = 0.80 \pm 0.05$. From these data we can conclude that in the case of $24^\circ$ the Bell’s inequality is violated for more than 17 standard deviations.

7. Conclusions

We have analyzed, both theoretically and experimentally, the generation of polarization-entangled photon pairs by parametric down-conversion from solid state CW lasers with small coherence time. In particular, we have analyzed in some detail a compact and low-cost setup based on a two-crystal scheme with Type-I phase matching. The effect of pump coherence time on the entanglement and the nonlocality has been studied as a function of the crystal length. The full density matrix has been reconstructed by quantum tomography and the proposed theoretical model is verified using a purification protocol based on a compensation crystal. We conclude that laser diode technology is of
interest in view of large scale application and that it is the characterization of the generated state that allows one to suitably tailor entanglement distillation protocols.

Acknowledgements

MGAP thanks Maria Bondani and Marco Genovese for useful discussions. We are also indebted with Stefano La Torre for his help in detector realization.

Appendix 1. Measurement of the coherence length

In this Appendix we experimentally verify that the spectrum of the down-converted signal is reduced when coincidence photon counts are performed, as a consequence of the transverse momentum conservation.

If we observe only a single photon of the generated pair, the part of the spectrum incident on the coupling device is described in practice by the mismatch function \(f_{\omega_0}\) defined in Equations (3) and (4). But if we observe both photons and measure the simultaneous counts between signal and idler, we will detect a spectrum with a smaller width, and therefore we have a greater coherence length of the radiation. This because if we have a very wide spectrum for the signal at a fixed angle of observation, the idler photons, correlated with the signal photons also by transverse momentum conservation, will be dispersed over an angle that can be wider with respect to the acceptance angle of the coupling device. Hence, the pair of coupling devices work as a filter limiting the spectral window for observation. For the purpose of a determination of this effective spectral width, we present here some measurements using interference methods. In particular we performed two series of measurements, the first relative to the direct counts on a single detector to find the width associated with \(f_{\omega_0}\), the second relative to the coincidence counts on the two detectors to determine the width of the corrected mismatch function \(f_{\omega_0}\) used in Equation (6).

In Figure 9 we show the experimental scheme (based on a single BBO crystal) employed for these types of measurements. An interferometer equal to that described in [6] is placed among the signal ray. This interferometer is easy to align and is a very stable device. In both types of counting measurements we expect to see interference fringes as a function of the delay time introduced by the interferometer.
between two optical paths, and within the radiation coherence time. In particular we would determine a greater coherence length in the case of coincidence counts with respect to the case of signal single counts.

The theoretical description of the interferometric experiment is as follows. In the case of a single photon observation, and with a crystal generating horizontal photons, the density matrix for the signal before the interferometer can be built by integrating over the idler frequency, and reads as:

$$\rho_1 = \int d\Omega f(\Omega^0 + \Omega)^2 |H, \omega_s\rangle_s \langle H, \omega|.$$ (23)

The density matrix after the interferometer follows by considering: (a) a polarization rotation of 45° due to the HWP plate placed before the first calcite crystal; (b) the delay time \(\tau\) introduced by the interferometer between the \(H\) and \(V\) parts; (c) the projection of these states over the axis of the final polarizer oriented at 45°, placed before the coupling device. The final state vector is easily obtained as:

$$\rho_1 = \int d\Omega f(\Omega^0 + \Omega)^2 \frac{1}{4} |1 + \exp(i\Omega \tau)|^2 |45^\circ, \omega_s\rangle_s \langle 45^\circ, \omega|. \quad (24)$$

The probability to observe a count on the detector is then proportional to:

$$P_1(\tau) = \int d\Omega' |\langle 45^\circ, \omega'| \rho_1 |45^\circ, \omega\rangle|^2 = \int d\Omega f(\Omega^0 + \Omega)^2 \frac{1}{4} |1 + \exp(i\Omega \tau)|^2.$$ (25)

from which it is clear that the pump does not participate in the creation of interference fringes. The width of the interference pattern representing count numbers as a function of the delay \(\tau\), is given by a factor similar to a Fourier transform of the down-converted amplitude spectrum; hence this width scales as the inverse of the spectral power width of the function \(f\).

In the case of signal and idler coincidence counting, the state vector is again derived from Equation (10), by taking only the \(H\) part and discarding the propagation factor. As before, after the passage in the interferometer, the state vector is given as:

$$|\Psi_2\rangle = \int d\Omega_0 d\Omega A(\Omega_0) \tilde{f}(\Omega^0 + \Omega)$$

$$\times \frac{1}{2} \left(1 + \exp(i\Omega \tau)\right) |45^\circ\rangle_s |H\rangle_{s'} |\Omega_0 - \Omega| \langle \Omega^0_0\rangle_s.$$ (26)

with the modified mismatch function \(\tilde{f}\). The probability of coincidence counts will be proportional to:

$$P_2 = \left| \int d\Omega_0 d\Omega' |\langle 45^\circ, \Omega_0'\rangle_s |\langle H, \Omega\rangle_s |\Omega_0 - \Omega| \langle \Omega^0_0\rangle_s \right|^2 = P_1 \left( f \Rightarrow \tilde{f} \right).$$ (27)

which is exactly the previous result in which \(f(\Omega^0 + \Omega)\) is replaced by \(\tilde{f}(\Omega^0 + \Omega)\). Hence, in this case the width of the interference curve is governed by the modified spectral power width \(\Delta\omega_s\) of \(\tilde{f}\).

In Figure 10 we show on the left the interference pattern obtained with signal single counts, using the BBO crystal of 3 mm length. The width of the curve is near 30 fs, corresponding to a down-converted spectrum of about 64 nm. On the right we show the pattern in the case of signal and idler coincidence counts: the coherence time is enlarged to 70 fs, corresponding to a spectral width of 27 nm. In both cases the coherence length is well below that of the pump light. These data are used to determine the appropriate correction factor \(R(\Delta\omega_s) = f(\omega_s)/f(\omega)\) in the definition of the wavefunction Equation (6).

**Appendix 2. Complete calculation of the delay times in state generation**

In deriving the delay time between \((HH)\) and \((VV)\) photons, we assumed state generation in the crystals’ middle. But in fact these states can be generated at any point in the inner of the crystals, therefore the propagation factors \(P(H)\) and \(P(V)\) must be position dependent. Let’s indicate with \(z_1\) and \(z_2\) the longitudinal coordinates of the internal generation points for the first crystal and for the second crystal, respectively. Referring to Figure 3, we now have
the following two equations for the propagation times $\tau_H$ and $\tau_V$:

$$\tau_H(z_1, z_2) = \frac{L_C - z_1}{V_p} + \frac{z_2}{V_p} + \frac{L_C - z_2}{V_0 \cos(\phi_1)},$$

$$\tau_V(z_1, z_2) = \frac{L_C - z_1}{V_0 \cos(\phi_1)} + \frac{L_C - z_2}{V_0 \cos(\phi_2)}. \quad (29)$$

Generally speaking, the state visibility $p$ would depend on the delay time $\Delta \tau(z_1, z_2) = \tau_H(z_1, z_2) - \tau_V(z_1, z_2)$. Because we do not have any information about the effective position in which a particular photon pair is generated, we consider an average over the possible positions, by integrating with a flat distribution probability:

$$p_2 = \frac{1}{L_c^2} \int dz_1 \int dz_2 \exp[-\Delta \tau(z_1, z_2)/\tau_c]. \quad (30)$$

In Figure 11 we show a comparison between the visibility for state generation in the crystals’ middle, and that obtained from the above formula. It is clear that there is some difference only for very small visibilities obtained with very long crystals.
